Abstract

Feature-based attention is the ability to selectively attend to a particular feature (e.g., attend to red but not green items while looking for the ketchup bottle in your refrigerator), and steady-state visually evoked potentials (SSVEPs) measured from the human EEG signal have been used to track the neural deployment of feature-based attention. Although many published studies suggest that we can use trial-by-trial cues to enhance relevant feature information (i.e., greater SSVEP response to the cued color), there is ongoing debate about whether participants may likewise use trial-by-trial cues to voluntarily ignore a particular feature. Here, we report the results of a preregistered study in which participants either were cued to attend or to ignore a color. Counter to prior work, we found no attention-related modulation of the SSVEP response in either cue condition. However, positive control analyses revealed that participants paid some degree of attention to the cued color (i.e., we observed a greater P300 component to targets in the attended vs. the unattended color). In light of these unexpected null results, we conducted a focused review of methodological considerations for studies of feature-based attention using SSVEPs. In the review, we quantify potentially important stimulus parameters that have been used in the past (e.g., stimulation frequency, trial counts) and we discuss the potential importance of these and other task factors (e.g., feature-based priming) for SSVEP studies.

INTRODUCTION

Attending to a specific feature leads to systematic changes in the firing rates of neurons that encode the relevant feature space. For example, when looking for a ripe tomato, the firing rate of neurons tuned to red will be enhanced and the firing rate of neurons tuned to other features will be suppressed (e.g., responses to green; Bartsch et al., 2017; Kiyonaga & Egner, 2016; Wang, Miller, & Liu, 2015; Störmer & Alvarez, 2014; Ipata, Gee, Gottlieb, Bisley, & Goldberg, 2006; Martinez-Trujillo & Treue, 2004). Although there is broad agreement that participants may learn to suppress irrelevant distractors with sufficient experience, there is disagreement about whether these behavioral suppression effects may be volitionally implemented on a trial-by-trial basis in response to an abstract cue (i.e., a “volitional account”), or if they instead are solely implemented via implicit or statistical learning mechanisms (i.e., a “priming-based” account). Consistent with a volitional or proactive account, some work has found that participants can learn to use a trial-by-trial cue to ignore a particular color (Zhang, Gapelin, & Carlisle, 2020; Carlisle & Nitka, 2019; Chang & Egeth, 2019; Concì, Deichsel, Müller, & Töllner, 2019; Reeder, Oliviers, & Pollmann, 2017; Arita, Carlisle, & Woodman, 2012; Moher & Egeth, 2012; for nuanced reviews, see van Moorselaar & Slagter, 2020; Geng, 2014).

However, other work has found that a specific color needs to be repeated over many trials to be suppressed, consistent with a priming or passive account (Won & Geng, 2020; Failing, Feldmann-Wüstefeld, Wang, Oliviers, & Theeuwes, 2019; Geng, Won, & Carlisle, 2019; Stilwell & Vecera, 2019; Cunningham & Egeth, 2016; Theeuwes, 2013; Vatterott & Vecera, 2012; Lamy, Antebi, Aviani, & Carmel, 2008).

Although many studies have examined the effects of feature-based suppression on later selection-related ERP markers such as the N2pc and Pd (Carlisle & Nitka, 2019; Donohue, Bartsch, Heinze, Schoenfeld, & Hopf, 2018; Arita et al., 2012; Sawaki & Luck, 2010), a key open question is whether trial-by-trial cues to ignore a color modulate earlier stages of visual processing. Recent work by Reeder et al. (Reeder et al., 2017) hypothesized that cues about which feature to ignore (i.e., “negative cues”) may down-regulate processing in visual cortex during the prestimulus period. Consistent with this hypothesis, they found that overall BOLD activity in early visual cortex was lower when participants were given a negative cue about the target color than when participants were given either a positive or neutral cue. One limitation of this study, however, is that the authors were unable to test whether these univariate effects were actually feature specific (as opposed to task-general anticipation). However, evidence from ERP studies suggests that feature-based attention modulates early visual processing in a feature-specific manner, as

indexed by the P1 component (Moher, Lakshmanan, Egeth, & Ewen, 2014; Zhang & Luck, 2009). Critically, however, these ERP studies used a design where the same target and distractor colors were repeated over many trial events. Thus, it is not clear whether feature-based attention can modulate early visual processing on a trial-by-trial basis, or if modulation of early visual processing is achieved primarily via intertrial priming (Lamy & Kristjánsson, 2013; Theeuwes, 2013). To attempt to address this gap, we conducted a preregistered experiment in which we measured steady-state visually evoked potentials (SSVEPs) while giving participants trial-by-trial cues to suppress feature information.

When visual input flickers continuously at a given frequency (e.g., one stimulus at 24 Hz and another at 30 Hz), the visually evoked potential in the EEG signal reflects these “steady states” and time-frequency analyses can be used to derive estimates of the strength of neural responses to each stimulus (Regan, 1977; Adrian & Matthews, 1954). The amplitude of the frequency-specific SSVEP response has been shown to be modulated by both spatial and feature-based attention (higher amplitude when attended; Müller et al., 2006; Chen, Seth, Gally, & Edelman, 2003; Pettet, Norcia, 2002; Müller, Teder-Sälejärvi, & Hillyard, 1998; Morgan, Hansen, & Hillyard, 1996). When participants are cued on a trial-by-trial basis to attend to a particular feature (e.g., color), the SSVEP amplitude is higher for the attended feature (Andersen, Hillyard, & Müller, 2008; Müller et al., 2006; Chen et al., 2003). Furthermore, the time-course of the SSVEP response to an attended color reveals an early enhancement followed by a suppressed response to the irrelevant, nonattended color (Forschack, Andersen, & Müller, 2017; Andersen & Müller, 2010).

Our primary manipulation was whether we cued participants to actively attend or to actively ignore a color on a trial-by-trial basis. We planned to use this method to track enhancement versus suppression of the SSVEP response and to test whether the time-course of enhancement and suppression varies with cue type. In the “attend cue” condition, participants were cued about the relevant color to attend. This condition was expected to replicate prior work examining the time-course of feature-based attention using SSVEPs (Andersen & Müller, 2010), whereby enhancement of the attended color is followed by suppression of the ignored color. In the “ignore cue” condition, we instead cued participants about which color to ignore. If participants can use a cue to directly suppress a color on a trial-by-trial basis independent of target enhancement (i.e., a strong version of a volitional suppression account), we predicted that the time-course of enhancement versus suppression of the SSVEP signal would be reduced or reversed (i.e., that suppression of the cued, to-be-ignored color may happen even before enhancement of the other color). Alternatively, if participants recode the “ignore” cue to serve as an indirect “attend” cue (e.g., “Since I’m cued to ignore blue, that means I should attend red”; Williams, Pratt, & Ferber, 2020; Beck & Hollingsworth, 2015; Becker, Hemsteger, & Peltier, 2015), then we predicted that target enhancement would always precede distractor suppression regardless of whether participants were cued to attend or ignore a particular color.

To preview the results, we were unable to fully test our hypotheses about the time-course of feature-based enhancement and suppression because we did not find evidence for an overall attention effect with our task procedures. Despite robust SSVEP amplitude (Cohen’s $d > 5$), we observed no credible evidence that the SSVEP response was higher for an attended versus unattended color in either cue condition. Positive control analyses revealed that our lack of SSVEP effect was not because of a complete lack of attention to the attended color: ERP responses (P3) to the targets were modulated by attention as expected (Adamian, Slaustaite, & Andersen, 2019; Andersen, Hillyard, & Müller, 2013; Andersen, Fuchs, & Müller, 2011). In light of our inconclusive results, we also performed a focused methodological review of key potential task differences between our work and prior work that may have resulted in our failure to detect the effect of feature-based attention on SSVEP amplitude. We considered whether task factors such as stimulus flicker frequency, sample size, stimulus duration, and stimulus color might have impacted our ability to observe an attention effect. No single methodological factor that we considered neatly explains our lack of effect. Given our results and literature review, we propose that future work is needed to systematically explore two key factors: (1) variation in feature-based attention effects across stimulus flicker frequencies and (2) the extent to which feature-based priming modulates SSVEP attention effects.

**METHODS**

**Preregistration and Data Availability**

We published a preregistered research plan on the Open Science Framework before data collection (osf.io/kfg9h/). Our raw data and analysis code are available online on the Open Science Framework at osf.io/ew7dv/.

**Participants**

Healthy volunteers ($n = 32$; 17 women, 15 men; mean age = 21.5 years [$\text{SD} = 3.84$, min = 18, max = 39]; handedness not recorded; corrected-to-normal visual acuity; normal color vision) participated in one 3.5- to 4-hr experimental session at the University of California San Diego campus and were compensated $15/hr. Procedures were approved by the University of California San Diego institutional review board, and all participants provided written informed consent. Inclusion criteria included normal or corrected-to-normal visual acuity, normal color vision, age between 18 and 60 years old, and no self-reported history of major neurological disorders (e.g., epilepsy, stroke). Data were excluded from analysis if there were fewer than 400 trials in
either cue condition (either because of leaving the study early or after artifact rejection). A sample size of 24 was preregistered, and artifact rejection criteria were preregistered (see EEG Preprocessing section for more details). After running each participant, we checked whether the data were usable (i.e., sufficient number of artifact-free trials) so that we would know when to stop data collection. To reach our final sample size ($n = 23$ participants with usable data), we ran 32 participants. Nine participants’ data were not used for the following reason: participants with an error in the task code ($n = 3$), participants who stopped the study early because of technical issues or to participants’ preferences ($n = 4$), and participants with too many artifacts ($n = 2$). Note, we were one participant short of our preregistered target sample size of 24 because data collection was suspended due to COVID-19. However, as our later power analyses will show, we do not believe the addition of one further participant would have meaningfully altered our conclusions.

**Stimuli and Procedures**

**Heterochromatic Flicker Photometry Task**

We chose perceptually equiluminant colors for each participant using a heterochromatic flicker photometry task. Participants viewed a large circular, flickering stimulus (8° radius) on a black screen (0.08 cd/m²). We generated five circular color spaces in CIELAB-space (International Commission on Illumination L*a*b*) with varying luminance (circles centered on: $L = 35−65$, $a = 0$, $b = 0$; five colors equally spaced around circle with radius = 35) for use in the task. Participants matched each of the five colors to a medium-gray reference color (red, green, blue = 105.6 105.6 105.6).

On each trial, the circular background was flickered between two different colors. One color was always medium-gray, and the other color was the to-be-matched color on that trial. The colors of circular background were phase reversed at a rate of 24 Hz, giving the appearance of a fast flicker when the subjective luminance values were not matched. On top of the flickering circular stimulus, small oriented bars were drawn in the medium-gray reference color (the bars changed locations at a rate of 1 Hz). The oriented bars served no purpose other than subjectively making it easier to discriminate fine-grained differences in luminance between the flickering colors (i.e., these bars gave secondary visual cues about equiluminance via the “minimally distinct border” phenomenon; Kaiser, 1988). Participants increased or decreased the luminance of the to-be-matched color (using up and down arrow keys) until the amount of perceived flicker was minimized—the point of perceptual equiluminance. The luminance starting value of the to-be-matched color was chosen at random on each trial. Once satisfied with their response, the participant pressed spacebar to continue to the next trial. Each to-be-matched color was repeated 3 times (15 trials total).

**Feature-based Attention Task**

All stimuli were viewed on a luminance-calibrated cathode ray tube monitor (1024 × 768 resolution, 120-Hz refresh rate) from a distance of ∼50 cm in a dimly lit room. Stimuli were generated using MATLAB 2016a and the Psychophysics toolbox (Kleiner et al., 2007; Brainard, 1997; Pelli, 1997). Participants rested their chin on a chin rest and fixated a central dot (0.15° radius) throughout the experiment. The stimulus was a circular aperture (radius = ∼9.5°) filled with 120 oriented bars (each bar ∼1.1° long and ∼.1° wide). Bars were centered on a grid and separated by ∼1 bar length such that they never overlapped with one another. On each individual frame (∼8.33 msec), this grid was randomly phase shifted (0.2π in $x$ and $y$ coordinates) and rotated (1.360°), thus giving the appearance of random flicker. To achieve SSVEP, half of the bars flickered at 24 Hz (three frames on, two frames off) and the other half flickered at 30 Hz (two frames on, two frames off). Because of the jittered rotation of bar positions and to the random assignment of colors to bars on each “on” frame, this means that the individual pixels that were “on” for each color varied from frame to frame. The unpredictable nature of each bar’s exact position is thus quite similar to unpredictable stimuli that have been used in past work (e.g., Andersen et al., 2008). For each “off” frame, no bars of that color were shown (e.g., if 24 Hz had an “on” frame and 30 Hz had an “off” frame, then only 60 of 120 bars would be shown on the black background). If both the 24- and 30-Hz bars were “off,” then a black screen would be shown on that frame. See Appendix A for an illustration of some sample frame-by-frame screenshots of the stimuli.

On each trial (Figure 1), the participants viewed the stimulus array of flickering, randomly oriented bars presented on a black background (0.08 cd/m²). Half of these bars were shown in one color (randomly chosen from the five possible colors), and the other half were in another randomly chosen color (with the constraint that the two sets of bars must be two different colors). During an initial baseline (1333 msec), participants viewed the flickering dots while they did not yet know which color to attend; during this baseline, the fixation point was a medium gray color (same as the reference color in the flicker photometry task). After the baseline, the fixation dot changed color, cuing the participants about which color to attend or ignore. In the “attend cue” condition, the color of the fixation point indicated which color should be attended. In the “ignore cue” condition, the color of the fixation point indicated which color should be ignored. These two conditions were blocked, and the order was counterbalanced across participants (further details below). During the stimulus presentation (2000 msec), participants monitored the relevant color for a brief “target event” (333 msec). During this brief target event, a percentage of lines in the relevant color will be coherent (iso-oriented). Critically, the orientation of each coherent target or distractor event was...
completely unpredictable (randomly chosen between 1° and 180°); thus, participants could not attend to a particular orientation in advance to perform the task. A target event occurred on 50% of trials, and participants were instructed to press the spacebar as quickly as possible if they detected a target event. Importantly, physically identical events (iso-oriented lines in a random orientation, 333 msec) could also appear in the distractor color (50% of trials). Participants were instructed that they should only respond to target events; if they erroneously responded to the distractor event, the trial was scored as incorrect. The target and/or distractor events could begin as early as cue onset (0 msec) and no later than 1667 msec after stimulus onset. Participants could make responses up to 1 sec into the intertrial interval. If both a target and distractor event were present, their onset times were separated by at least 333 msec.

To ensure that the task was effortful for participants, the coherence of the lines in the target stimulus was adapted at the end of each block if behavior was outside the range of 70%–85% correct. At the beginning of the session, the target had 50% coherent iso-oriented lines. If accuracy over the block of 80 trials was > 85%, coherence decreased by 5%. If block accuracy was < 70%, coherence increased by 5%. The maximum allowed coherence was 80% iso-oriented lines (so that participants would not be able to simply individuate and attend a single position to perform the task) and the minimum allowed coherence was 5%. The presence and absence of target and distractor events was balanced within each block yielding 4 subconditions within each cue type (25% each): (1) target event + no distractor event, T1D0 (2) no target event + distractor event, T0D1 (3) target event + distractor event, T1D1 (4) no target event + no distractor event, T0D0.

Participants completed both task conditions (attend cue and ignore cue). The two conditions were blocked and counterbalanced within a session (i.e., half of participants performed the “attend cue” task for the first half of the session and the “ignore cue” task for the second half of the session). Each block of 80 trials took approximately 6 min 50 sec. Participants completed 18 blocks (nine per condition) for 720 trials per cue condition. Note, we originally planned for 20 blocks (10 per condition) in the preregistration, but the block number was reduced to 18 after the first few participants did not finish all blocks.

Summary of Deviations from the Registered Procedures
As described in-line above, there were some minor deviations from the preregistration: (1) We made changes to the preregistered task code to fix errors that we discovered while running the first three participants (e.g., incorrect cues and behavioral feedback in the “ignore cue” condition). (2) We included code for eye-tracking, which allowed us to give participants automated real-time feedback if they blinked when they were not supposed to, that is, during the stimulus period. (3) We reduced the total number of experimental blocks from 20 (10 per cue condition) to 18 (nine per cue condition) because of time constraints. (4) We had to prematurely stop data collection at n = 23 of...
24 because of COVID-19. (5) We forgot to specify a specific statistical test for quantifying the robustness of overall SSVEPs in the Checking That an SSVEP is Elicited at the Expected Frequencies before Collecting the Full Sample section, so we have described our justification for the statistical tests we present here. (6) Because of unanticipated failure to detect an overall attention effect, we performed additional non-preregistered control analyses to attempt to rule out possible explanations of this null effect (see Non-preregistered Control Analyses section).

EEG Preprocessing

Continuous EEG data were collected online from 64 Ag/AgCl active electrodes mounted in an elastic cap using a BioSemi ActiveTwo amplifier (Cortech Solutions). An additional eight external electrodes were placed on the left and right mastoids, above and below each eye (vertical EOG), and lateral to each eye (horizontal EOG). Continuous gaze-position data were collected from an SR Eyelink 1000+ eye-tracker (sampling rate: 1000 Hz; SR Research). We also measured stimulus timing with a photodiode affixed to the upper left-hand corner of the monitor (a white dot flickered at the to-be-attended color frequency; the photodiode and this corner of the screen were covered with opaque black tape to ensure it was not visible). Data were collected with a sampling rate of 1024 Hz and were not downsampled off-line. Data were saved unfiltered and unreferenced (see Kappenman & Luck, 2010) and then referenced off-line to the algebraic average of the left and right mastoids, low-pass filtered (< 80 Hz), and high-pass filtered (> .01 Hz). Artifacts were detected using automatic criteria described below, and the data were visually inspected to confirm that the artifact rejection criteria worked as expected. We excluded participants with fewer than 400 trials remaining per cue condition.

Eye Movements and Blinks

We used the eye-tracking data and the horizontal EOG/vertical EOG (VEOG) traces to detect blinks and eye movements. Blinks were detected on-line during the task using the eye tracker. If a blink was detected (i.e., missing gaze position returned from the eye tracker), the trial was immediately terminated and the participant was given feedback that they had blinked (i.e., the word "blink" was written in white text in the center of the screen). If eye-tracking data could not be successfully collected (e.g., calibration issues), the VEOG trace was used to detect blinks and/or eye movements during on-line artifact rejection. To do so, we used a split-half sliding window step function (Luck, 2005; window size = 150 msec, step size = 10 msec, threshold = 30 microvolts.) We also used a split-half sliding-window step function to check for eye-movements in the gaze-coordinate data from the eye-tracker (window size = 80 msec, step size = 10 msec, threshold = 1°) and in the horizontal EOG (window size = 150 msec, step size = 10 msec, threshold = 30 microvolts) and to detect blinks and/or eye movements in the VEOG.

Drift, Muscle Artifacts, and Blocking

We checked for drift (e.g., skin potentials) by comparing the absolute change in voltage from the first quarter of the trial to the last quarter of the trial. If the change in voltage exceeded 200 microvolts, the trial was rejected for drift. In addition to slow drift, we also checked for sudden, step-like changes in voltage with a sliding window (window size = 250 msec, step size = 20 msec, threshold = 200 microvolts). We excluded trials for muscle artifacts if any electrode had peak-to-peak amplitude greater than 200 microvolts within a 15-msec time window (step size = 10 msec). We excluded trials for blocking if any electrode had ~120 msec during which all values within 1 microvolt of each other (sliding 200-msec window, step size = 50 msec).

Preregistered SSVEP Analyses

General Method for SSVEP Quantification

We planned to quantify the SSVEP response by filtering the data with a Gaussian wavelet function. First, we calculated an average ERP for each condition at electrodes of interest (O1, Oz, O2). We chose these three electrodes based on large SSVEP modulations at these sites in prior work (e.g., Itthipuripat, Garcia, & Serences, 2013; Müller et al., 2006). After calculating an ERP for each condition, we filtered the data with a Gaussian wavelet functions (frequency-domain) with .1 fractional bandwidth to obtain frequency-domain coefficients from 20 to 35 Hz in 1-Hz steps. The frequency-domain Gaussian filters thus had an FWHM that varied according to frequency, as specified by the 0.1 fractional bandwidth parameter (1-Hz filter = FWHM of .1 Hz, 20-Hz filter = FWHM of 2 Hz, 30-Hz filter = FWHM of 3 Hz, etc.). For a similar analytic approach, see Rungratsameetaweena, Itthipuripat, Salazar, and Serences (2018); Itthipuripat et al. (2013); and Canolty et al. (2006). Signal-to-noise ratio (SNR) for each SSVEP frequency was calculated as the power at a given frequency divided by the average power of the two adjacent frequencies on each side. For example, SNR of 24 Hz would be calculated as the power at 24 Hz divided by the average power at 22, 23, 25, and 26 Hz. We also preregistered an analysis plan for examining the time-course of SSVEP amplitude. However, because our data failed to satisfy preregistered prerequisite analyses, we do not report these time-course effects here (for completeness, we show the time-course of SNR in Figure S3).

Checking That an SSVEP is Elicited at the Expected Frequencies before Collecting the Full Sample

At n = 5, we planned to confirm that our task procedure successfully produced reliable SSVEP responses (i.e., check
that we observed peaks at the correct stimulus flicker frequencies. If our task procedures failed to elicit an SSVEP at the expected frequencies, we had planned to stop data collection and alter the task to troubleshoot the problem (optimize timing, choose different flicker frequencies, make stimuli brighter, etc.). We planned to begin data collection over again if we failed this trouble-shooting step. Note that, at this early stage, we only verified if the basic method worked (SSVEP frequencies were robust): We did not test whether any hypothesized attention effects were present, as this could inflate our false discovery rate (Kravitz & Mitroff, 2017). Also note that in the original preregistration, we failed to specify what test we would run to determine if SSVEP frequencies were robustly represented in the EEG signal. Theoretical chance for SNR would be 1, so the simplest test would be to compare the SNR for our stimulation frequencies (24 and 30 Hz) to 1 using a t test, which we report. However, it is often better to compare to an empirical baseline with a reasonable amount of noise (Combrisson & Jerbi, 2015). As such, we opted to also compute an effect size comparing the SNR for our stimulation frequencies to all other frequencies (with the exception that we did not use frequencies ± 2 Hz of 24 or 30 Hz as baseline values, because SNR was calculated as the power at frequency F divided by the power in the two adjacent 1-Hz bins).

Checking Achieved Power for the Basic Attention Effect

Without adequate power for the basic attention effect, we would not be able to robustly interpret the time-course of enhancement versus suppression. At the full sample size, we thus planned to check whether we had sufficient achieved power for the overall attention effect (≥ 80% power for attended vs. ignored color collapsed across the entire stimulus period) as a prerequisite for interpreting the time-course of enhancement and suppression.

Checking If A Priori Electrodes Are Reasonable

We chose a priori to analyze the SSVEP at electrodes O1, Oz, and O2 (Rungratsameetaweemana et al., 2018; Itthipuripat et al., 2013), but we planned to plot the topography of SSVEP modulation across all electrodes to check that these a priori electrodes were responsive to the SSVEP manipulation. If these electrodes were not responsive to the SSVEP, we planned to perform a cluster-based permutation test to select a new set of electrodes.

Checking if Target and/or Distractor Presence Alters Results

Our core analyses planned to use all trials for each condition (e.g., target event present or absent, distractor event present or absent). To confirm that the act of making a response did not contaminate the SSVEP results, we planned to compare SSVEPs for each of the four subconditions (the four possible combinations of target present/absent and distractor present/absent). We predicted that the main SSVEP attention effect (entire stimulus period) would not be different across these four conditions. However, if we found an effect of target or distractor presence on the main SSVEP attention effect, then we planned to use only the trials without target or distractor events for the time-course analyses (as has been done in prior work, e.g., Andersen & Müller, 2010).

Checking if the Distance between the Target and Distractor Color Alters Results

We planned to test whether the magnitude and time-course of attentional selection differs as a function of target-distractor color similarity (∼72° vs. ∼144° separation between the attended and ignored color). Prior work found that it was more difficult to simultaneously attend opposite colors (180° apart) than to simultaneously attend two moderately spaced colors (60° apart; Chapman, Geweke, & Störmer, 2019; Geweke, Li, & Störmer, 2018; Störmer & Alvarez, 2014). Given this result, we predicted that it should be easier to suppress a color that is drastically different from the target color (and behavioral accuracy should likewise be higher for the 144° condition).

Additional Non-preregistered SSVEP and ERP Control Analyses

We did not anticipate our failure to find an overall attention effect with these task procedures and set of preregistered “sanity check” analyses described above. To further understand the lack of SSVEP attention effect, we performed additional non-preregistered control analyses.

Positive Control: Frequency Analysis of the Photodiode Voltage

During the recording, a photodiode was used to ensure that the flicker frequencies were faithfully presented, and the photodiode recorded voltage fluctuations induced by a small white dot that flickered at the to-be-attended target frequency on each trial. The electrical activity from the photodiode was recorded as an additional “electrode” in the data matrix (with the structure: trials × electrodes × time points). Thus, we performed a fast Fourier transform (FFT; MATLAB function fft.m) to ensure that the trial indexing and FFT aspects of our analysis were correct. If these aspects of the analysis were correct, we should expect a near-perfect modulation of photodiode FFT amplitude by attention condition as only the flicker frequency of the attended stimulus was tagged. For one participant, the photodiode was not plugged in (leaving 22 participants for this analysis).
Analysis Control: Using a More Similar Frequency Analysis Procedure to Prior Published Work

Because we were interested in characterizing a time-course effect, we chose to use a Gaussian wavelet procedure to quantify power for each frequency of interest. However, given the lack of overall attention effect, we were not able to meaningfully look at the time-course effects. Thus, we additionally used an FFT to measure SSVEP amplitude during the entire stimulus period. This method is more commonly used in prior published work (e.g., Andersen & Müller, 2010; Andersen et al., 2008). After prior work, we used the entire stimulus epoch starting from 500 msec onward (500 to 2000 msec), we detrended the data, and we zero-padded this time window (2048 points) to precisely estimate our frequencies.

Positive Control: Analysis of ERP (P3) for an Attention Effect

Prior work has found that attention-related SSVEP modulations are accompanied by changes to ERPs associated with target selection and processing. To measure the P3, we calculated ERPs time-locked to the target or distractor onset (baseline to −200 to 0 msec relative to target onset). We included trials where there was only one target or distractor event on that trial, to avoid the possibility of overlap between the two signals. We calculated P3 voltage at electrodes Pz and POz during the time window 450–700 msec after target onset, similar to prior work (Adamian et al., 2019; Andersen et al., 2011, 2013).

RESULTS

Behavior

Participants were overall accurate at the task (percent correct = 65.7%, $d'=1.25$) and were significantly above chance (percent correct > 50%, $p<.001$; $d' > 0, p < .001$). There was no overall significant effect of Cue condition (attend cue vs. ignore cue) on performance, $p = .85$, but analysis of target-present trials suggested that participants could more quickly use attend cues than ignore cues ($p < .05$ when the target appeared between 0 msec and 275 msec, but $p > .05$ if the target appeared after 275 msec; Appendix B).

Average percent correct was lower than our prespecified target range of 70–85%, meaning that most participants saw targets and distractors that were maximally coherent (80% iso-oriented lines) for the majority of blocks (mean coherence of the target/distractor events $= 73.7\%$, $SD = 5.08\%$). Although overall accuracy was slightly out of the range we had expected when planning the study, participants were well above chance and they saw targets with coherence values typical of prior work (Andersen et al., 2008, 2011; Andersen & Müller, 2010).

Preregistered SSVEP Results

We first confirmed that our SSVEP procedure was effective at eliciting robust, frequency-specific modulations of the EEG signal. After collecting the first five participants, we checked that overall SSVEP amplitudes for our two target frequencies (24 and 30 Hz) were robust when collapsed across conditions (Figure 2A) before proceeding with data collection. We indeed found that the SSVEP signal was robust during the stimulus period even with $n = 5$ for both the 24-Hz frequency (mean SNR = 4.45, $SD = .14$, SNR > 1: $p < .001$) and for the 30-Hz frequency (mean SNR = 2.97, $SD = .15$, SNR > 1: $p < .001$). These values were similar for the full $n = 23$ sample (Figure 2B). To compute an effect size, we compared SNR values for each target frequency (24 and 30 Hz) to the SNR values for each baseline frequency (frequencies from 3 to 33 Hz not within ± 2 Hz of 24 or 30 Hz). SNR values for the target frequencies were significantly higher than baseline, mean Cohen’s $d = 5.10$ ($SD = 1.11$) and 5.99 ($SD = 2.66$), respectively (see Appendix C). As planned, we also confirmed that the electrodes we selected a priori (O1, Oz, and O2) were reasonable given the topography of overall SSVEP amplitudes (i.e., they fell approximately centrally within the brightest portion of the heat map; Figure 2C–D).

Next, we checked for a basic attention effect, defined as a larger amplitude response evoked by the attended frequency compared to the ignored frequency. Note, for the sake of clarity, all conditions are translated into “attend” terminology. That is, if a participant was cued to “ignore blue” (24 Hz) during the “ignore cue” condition (and the other color was red and 30 Hz), this will instead be plotted as “attend red” (30 Hz). Figure 3 shows the Gaussian wavelet-derived frequency spectra during the stimulus period (500–2000 msec) as a function of cue type (attend vs. ignore) and attended frequency (attend 24 Hz or attend 30 Hz). We found a main effect of measured frequency, whereby SNR was overall higher for 24 versus 30 Hz, $F(1, 22) = 57.89$, $p < .001$, $\eta_p^2 = .73$. However, we found no main effect of attended frequency ($p = .27$) or cue type ($p = .83$), and we found no significant interactions ($p \geq .18$). Collapsed down to a paired t test, the observed effect size for attended versus unattended SNR values was Cohen’s $d = .03$. To detect an effect of this size with 80% power ($1 - \beta = .8; \alpha = .05$) would require a sample size $n > 7000$. Given that we did not find an overall attention effect, we did not analyze or interpret analysis of the SSVEP time-course. However, for completeness, we have shown the time-course in Appendix D.

Although we preregistered that we would analyze all trials (those with and without target/distractor events), most prior studies have included only trials without any target or distractor events in the main SSVEP analysis (e.g., Andersen et al., 2008; Müller et al., 2006). To ensure that our null result was not because of this analysis choice, we also planned in our preregistration to examine the SSVEP attention effect for trials with and without target and distractor
events. When restricting our analysis to only trials without targets or distractors (25% of the 1440 trials, or 360 trials total before artifact rejection), we likewise found no attention effect. As before, we found a main effect of Measured frequency (24 > 30 Hz), \( p < .001 \), but no effect of Cue condition \( (p = .053) \) or Attended frequency \( (p = .073) \), and, most critically, we found no interaction between Measured frequency and Attended frequency \( (p = .33) \). Frequency spectra for all combinations of target and distractor presence are shown in Appendices E and F.

Finally, we also preregistered that we would check whether the similarity of the target and distractor colors

Figure 2. SSVEP amplitude at the expected frequencies (collapsed across all experimental conditions). (A) Power as a function of frequency during the stimulus period at electrodes O1, O2, and Oz for the first five participants. As expected, we observed robust peaks at the stimulated frequencies (24 and 30 Hz). (B) Power as a function of frequency for the stimulus period for the full sample \( (n = 23) \). (C–D) Topography of SNR values for 24 Hz (C) and 30 Hz (D) for all participants collapsed across all experimental conditions. Color scale indicates SNR. As expected, the a priori electrodes O1, O2, and Oz (magenta circles) showed robust SNR during the stimulus period.

Figure 3. Overall attention effect in the attend cue and ignore cue conditions. (A–B) Frequency spectra in the attend cue (A) and ignore cue (B) conditions during the stimulus period. Although we observed expected peaks at 24 and 30 Hz, this SSVEP response was not modulated by the attention manipulation. (C–D). Violin plots of the SNR at the SSVEP frequencies in the attend cue (C) and ignore cue (D) conditions.
(72° vs. 144° apart on a circular color wheel; Figure 1B) would modulate the SSVEP attention effect. We likewise found that the similarity of the distractor colors did not significantly modulate the SSVEP response, and we found no attention effect (interaction of measured frequency and attended frequency) in either color distance condition ($p \geq .26$; Appendix G).

**Non-preregistered Control Analyses**

We conducted additional control analyses to rule out possible sources of our failure to find an attention effect. First, we examined the photodiode recording to rule out any failures because of trial indexing. The photodiode measured the luminance of a white dot that flickered at the attended frequency on each trial. As expected, performing an FFT on the photodiode time-course thus yielded near-perfect tracking of the attended frequency (Figure 4A–B, $p < .001$). On the other hand, we again found null results for the main attention manipulation (Figure 4C–F) when using an FFT analysis that more closely followed prior work. We ran a repeated-measures ANOVA on the SNR values during the stimulus period, including the factors Measured frequency (24 Hz, 30 Hz), Attended frequency (24 Hz, 30 Hz), and Cue type (attend, ignore). We found no main effect of Measured frequency ($p = .91$), Attended frequency ($p = .45$), or Cue type ($p = .54$), and we found no significant interactions ($p \geq .38$). However, the average SNR of the stimulus frequencies was overall robust ($M = 4.45, SD = 1.45$, greater than chance value of 1; $p < 1 \times 10^{-9}$), so our inability to observe the attention effect was not because of lack of overall SSVEP signal. Likewise, we

**Figure 4.** FFT analysis of the photodiode and SSVEPs at attended and unattended frequencies during the stimulus period (500–2000 msec). (A–B) As a positive control for our analysis pipeline, we performed an FFT analysis on the photodiode trace. The photodiode recorded a flickering white dot at the attended frequency on each trial. As expected, this provides a near-perfect tracking of the attended frequency in both the attend cue condition (A) and the ignore cue condition (B). (C–F) To ensure our null effect was not because of using Gaussian wavelets rather than an FFT, we repeated the main analysis with an FFT. Frequency spectra for the attend cue condition (C) and ignore cue condition (D) reveal an overall robust SSVEP signal at 24 and 30 Hz, but no modulation by attention. Likewise, violin plots of SNRs again show robust signal but no modulation by attention in either the attend cue condition (E) or the ignore cue condition (F).
ran an additional analysis to ensure that our choice of pre-registered choice of SNR measure did not explain our null result (Appendix H).

Given that some work has reported significant effects only for the second harmonic (e.g., Vissers, Gulbinaite, van den Bos, & Slagter, 2017; Kim, Grabowecky, Paller, Muthu, & Suzuki, 2007), we likewise examined SSVEP amplitude at 48 and 60 Hz, with the caveat that the 60-Hz harmonic is contaminated by line noise (Appendices I and J). We found no significant attention effects for either second harmonic frequency. We also reran the FFT analysis with other electrode-selection methods to ensure our a priori choice of electrodes did not impede our ability to observe an effect. We found no evidence that electrode choice led to our null effect, as exploiting information from all 64 electrodes by implementing rhythmic entrainment source separation (RESS) likewise yielded null effects (Appendices K and L; Cohen & Gulbinaite, 2017). To ensure that inconsistent task performance did not lead to null effects, we repeated the main FFT analysis on only accurate trials. We likewise found null attention effects when analyzing only accurate trials (Appendix M).

Finally, we tested whether phase consistency, rather than power, may track attention in our task (e.g., Nunez, 2001). We performed an FFT on single trials rather than on condition-averaged waveforms, and we extracted single-trial phase values. We calculated a phase-locked index (PLI) by computing mean-resultant vector length on each condition’s histogram of single-trial phase values. Mean-resultant vector length ranges from 0 (fully random values) to 1 (perfectly identical values); for reference, see Zar (2007). We found no effect of attention on this PLI (Appendix N).

Positive Control: Analysis of ERP (P3b) for an Attention Effect

Consistent with prior work, we found a significantly larger P3 component for target onsets compared to distractor onsets (Figure 5). A repeated-measures ANOVA with within-subject factors Cue type (attend cue or ignore cue) and Event type (target or distractor onset) revealed a robust main effect of Event type (target > distractor), $F(1, 22) = 51.64, p < 1 \times 10^{-5}$, $\eta^2_p = .70$, and a main effect of Cue type (attend > ignore), $F(1, 22) = 4.96, p = .037, \eta^2_p = .18$, but no interaction between Event type and Cue type ($p = .65$). Control analyses confirmed this P3 modulation was not because of differential rates of making a motor response for targets and distractors (Appendix O). The main effect of Event type (target > distractor) remained when analyzing only trials where participants made a motor response ($p < .001$). Thus, the P3 was overall larger for target than distractor events, consistent with prior work that found this ERP attention effect alongside an SSVEP attention effect.

Focused Review of Feature-based Attention Studies Using SSVEPs

Given that our results are inconsistent with prior work, we conducted a focused review to try to pinpoint critical methodological differences that may have led to our failure to replicate a basic attention effect on SSVEP amplitude in this specific task. To do so, we first read review papers to identify an initial set of empirical studies employing a feature-based attention manipulation and SSVEPs (Norcia, Appelbaum, Ales, Cottereau, & Rossion, 2015; Andersen, Müller, & Hillyard, 2012; Vialatte, Maurice, Dauwels, & Cichocki, 2010). From this initial set of papers, we used Google Scholar to check citations and citing papers for mention of the terms feature-based attention and SSVEPs. Our inclusion criteria included: (1) Published journal paper (2), healthy young adults, (3) SSVEPs were measured from either an EEG or magnetoencephalography signal, and (4) a feature-based attention manipulation was included.

We defined “feature-based attention manipulation” as having the following characteristics: (1) Participants were cued to attend a feature(s) within a feature dimension (e.g., attend red, ignore blue) rather than across a feature dimension (e.g., attend contrast, ignore orientation). (2) The attended and ignored features were both frequency-tagged in the same trials (rather than only one feature tag per trial). (3) Each frequency was both “attended”

![Figure 5. P3 amplitude at electrodes Pz and POz. (A) P3 amplitude in the attend cue condition, as a function of whether the event onset (iso-oriented lines) was a target that should be reported or a distractor that should be ignored. (B) P3 amplitude in the ignore cue condition. Shaded error bars represent standard error of the mean; the gray rectangle indicates the time period used for the statistical tests.](Image)
and “ignored” on different trials, so that the amplitude of a given frequency could be examined as a function of attention. (4) The task could not be performed by adopting a strategy of splitting spatial attention to separate spatial locations.

After applying these screening criteria, some of the studies that we initially identified were excluded (brackets indicate exclusion reason(s)): Appelbaum & Norcia, 2009 [1, 4]; Boylan, Kelly, Thigpen, & Keil, 2019 [3]; Bridwell & Srinivasan, 2012 [2, 3]; Clementz, Wang, & Keil, 2008 [3]; Garcia, Srinivasan, & Serences, 2013 [1, 4]; Hasan, Srinivasan, & Grossman, 2017 [2]; Ithhipuripat, Deering, & Serences, 2019 [1]; Talsma, Doty, Strowd, & Woldorff, 2006 [1, 4]; Thigpen, Petro, Oschwald, Oberauer, & Keil, 2019 [4]; Vergheese, Kim, & Wade, 2012 [1, 4]).

We identified 34 experiments from 28 unique papers (Appendices P–S) meeting our inclusion criteria. From these experiments, we quantified variables such as the number of participants, number of trials, frequencies used, and the presence or absence of an attention effect in the expected direction (attended > ignored). If more than one group of participants was used (e.g., an older adults group), then we included the study but only quantified results for the healthy young adult group (Quigley & Müller, 2014; Quigley, Andersen, Schulze, Grunwald, & Müller, 2010).

**Task Used in Each Study**

The tasks used in these studies fell broadly into one of four categories: (1) a competing gratings task, (2) a whole-field flicker task, (3) a hemifield flicker task, and (4) a central task with peripheral flicker.

In the competing gratings task (Appendix P), participants viewed a stream of centrally presented, superimposed gratings (e.g., a red horizontal grating and a green vertical grating). Because colored, oriented gratings were typically used, participants could thus generally choose to attend based on either one or both features (color and/or orientation). Each grating flickered at its own frequency (e.g., green grating shown at 7.41 Hz, red grating shown at 8.33 Hz, as in Chen et al., 2003). Because the gratings were superimposed, on any given frame, only one of the two gratings was shown. On frames where both gratings should have been presented according to their flicker frequencies, a hybrid “plaid” stimulus was shown. Studies using a competing gratings task include Keitel and Müller (2016); Allison et al. (2008); Wang, Clementz, and Keil (2007); and Chen et al. (2005).

In the whole-field flicker task (Appendix Q), participants viewed a spatially global stimulus composed of small, intermingled dots or lines. Typically, half of the dots or lines were presented in one feature (e.g., red) and the other half of the lines were presented in another (e.g., blue); each set of dots flickered at a unique frequency. Although the most common attended feature was color, some task variants included (1) attending high or low contrast stimuli (2), attending a particular orientation, or (3) attending a particular conjunction of color and orientation. The whole-field flicker task was the most common task variant, and it is also most similar to the task performed here. Studies using a whole-field flicker task include Steinhauser and Andersen (2019); Martinovic and Andersen (2018); Martinovic, Wuerger, Hillyard, Müller, and Andersen (2018); Forschack et al. (2017); Andersen, Müller, and Hillyard (2009, 2015); Quigley and Müller (2014); Andersen, Müller, and Martinovic (2012); Andersen and Müller (2010); Quigley et al. (2010); Zhang et al. (2010); Andersen et al. (2008); and Müller et al. (2006).

In the hemifield flicker task (Appendix R), participants viewed a stimulus within each hemifield, and each stimulus was composed of small, intermingled dots or lines. Often, these studies included both a feature-based attention manipulation and a spatial attention manipulation (e.g., attend red on the left-hand side). However, the feature-based attention task could not be achieved with spatial attention alone, as participants needed to attend to a particular color and ignore a distractor color within the attended hemifield. In addition, the unattended hemifield could often be used to track the spatially global spread of feature-based attention. Studies using a hemifield flicker task include Adamian et al. (2019); Müller, Gundlach, Forschack, and Brunnerlooh (2018); Störmer and Alvarez (2014); and Andersen et al. (2011, 2013).

Finally, in the central task with peripheral flicker (Appendix S), participants performed a task near fixation (e.g., visual search), and feature-based attention was measured indirectly via a peripheral flickering stimulus (i.e., this design took advantage of the spatially global spread of feature-based attention; White & Carrasco, 2011; Säenz, Buraças, & Boynton, 2002, 2003). Studies using a central task with peripheral flicker include Chu and D’Zmura (2019); Jiang, Wu, and Gao (2017); Painter, Dux, and Mattingley (2015); and Painter, Dux, Travis, and Mattingley (2014).

**Sample Size, Trial Counts, and Stimulus Duration**

First, we examined whether insufficient power could have led to our failure to detect an attention effect. Both sample size and the number of trials per condition are critical for determining power (Baker et al., 2020; Clayson, Carbine, Baldwin, & Larson, 2019; Boudewyn, Luck, Farrens, & Kappenman, 2018; Button & Munafo, 2017; Thigpen, Kappenman, & Keil, 2017; Thigpen, Kappenman, & Keil, 2017; Button et al., 2013). The number of studies employing each task variant is plotted in Figure 6A, the number of participants per experiment is plotted in Figure 6B, the number of trials per experiment is plotted in Figure 6C, and stimulus duration is plotted in Figure 6D. Bars are color coded according to whether each experiment overall found an expected attention effect (attended > ignored), a reverse attention effect (ignored > attended), mixed results across conditions within the experiment, or ambiguous results (three studies: Pei et al., 2002: reported statistics for the harmonics but not the
fundamental frequency; Allison et al., 2008: missing formal statistical tests; Martinovic et al., 2018: statistical tests measured if attention effect differed between conditions, but did not formally test that the attention effect was overall significant). Our study had \( n = 23 \), 1440 total trials per participant (720 trials per cue condition), and a stimulus duration of 2 sec. In comparison to the literature, these factors are unlikely to explain our failure to find an effect. On average, prior studies had a median sample size of \( n = 15 \) (SD = 4.1, min = 9, max = 23) and a median trial count of 440 (SD = 314.2, min = 8, max = 1600) and a median stimulus duration of 4.1 sec (SD = 37.35, min = 1 sec, max = 120 sec). Likewise, our trial counts were reasonable when we restricted our analysis to trials without targets or distractors (360 trials total; 180 trials per condition) relative to this estimated value for the literature (median = 96 trials per condition, SD = 95.6, min = 4, max = 400). Upon initially plotting the data, we noticed that studies using the competing gratings task produced inconsistent results, with as many experiments showing a mixture of effects across conditions, overall reversed effects (ignored > attended), and null effects (two studies in each category). We think this inconsistency is most likely because of the below-average trial counts for these studies (median of only \( \sim 8 \) trials; Boudewyn et al., 2018).

**Percentage of Trials Where an Attended Feature Was Repeated**

Next, we examined the percentage of trials where the attended feature was repeated (e.g., if the attended color was red on trial \( n \), what was the chance that red would also be attended on trial \( n + 1 \)?). The priming-based account of feature-based attention posits that participants cannot use trial-by-trial cues to enhance a particular feature, but rather, feature-based enhancement happens automatically when a particular feature is repeated (Theeuwes, 2013). Thus, if there is a substantial proportion of trials where the repeated color was attended (e.g., with two possible colors, both the attended and ignored color will be repeated on 50% of trials), then the observed attentional enhancement effects might be driven primarily by incidental repetitions of attended features. In our study, we used five different colors to reduce the potential effect of intertrial priming on the observed SSVEP attention effects (20% repeats of the attended color, 4% repeats of the attended color and the ignored color). We quantified the approximate percentage of trials on which an attended feature on one trial is repeated on the next trial (within a given block of trials). In some studies, participants were cued to attend more than one feature on a given trial, or they sometimes attended to
a conjunction of features. In these cases, we calculated the expected number of repeats for either of the two attended features based on the total number of conditions (Martinovic et al., 2018; Andersen et al., 2008, 2013, 2015).

Figure 6E shows a histogram of the percentage of trials that repeated an attended feature. In two studies, the to-be-attended color was held constant on each block (100% repeats; Jiang et al., 2017; Painter et al., 2014). In the majority of the remaining studies, only two unique features were used so the percentage of trials where the attended feature was repeated was, on average, quite high (overall median = 50%, $SD = 27.4\%$, min = 0%, max = 100%). Finally, in three studies, the attention conditions were perfectly alternated (0% repeat trials; Allison et al., 2008; Wang et al., 2007; Chen et al., 2003). Consistent with a priming account, 81% of the studies with a high percentage of repeats showed a consistent positive attention effect, whereas none of the studies with 0% repeat trials showed a consistent positive attention effect. However, we think the inconsistent effects in the studies with 0% repeats might be equally attributed to their low trial counts (median = 8 trials per condition; Boudewyn et al., 2018). Only one study had a similar proportion of repeats as this study (Störmer & Alvarez, 2014). Störmer and Alvarez found a significant attention effect while using five unique colors (intermixed randomly from trial to trial). The findings by Störmer and Alvarez provide evidence against the feature-based priming account and suggest the task factor “number of colors” cannot definitively explain our inability to observe an attention effect. However, given the lack of extant work using unpredictable color cues, we think future, systematic work is needed to determine the degree to which intertrial priming effects may modulate the size and reliability of feature-based attention effects.

SSVEP Frequencies

We examined frequencies that have been most commonly used in the literature. In our study, we chose relatively high frequencies (24 and 30 Hz) to have increased temporal resolution for detecting potential time-course effects. In addition, some have argued that using higher frequencies as advantages for driving a more localized portion of visual cortex, as opposed to broadly driving visual, parietal, and frontal cortex when using lower frequencies in the theta/alpha bands (i.e., ~7–12 Hz; Ding, Sperling, & Srinivasan, 2006; Srinivasan, Bibi, & Nunez, 2006). For the purposes of temporal resolution, earlier work examining the time-course of spatial attention with SSVEPs used the frequencies 20 and 28 Hz (Müller, Teder-Sälejärvi, et al., 1998). However, upon reviewing the feature-based attention literature, we found that our chosen frequencies were outside the range that has previously been used with a feature-based attention task (Figure 6F; median = 10 Hz, $SD = 3.6$ Hz, min = 2.4 Hz, max = 19.75 Hz). Thus, it is possible that feature-based attention, unlike spatial attention, cannot be easily tracked with flicker frequencies above ~20 Hz. Although some studies have argued that feature-based attention effects do not qualitatively appear to vary with frequency (Steinhauser & Andersen, 2019; Martinovic et al., 2018), the vast majority of reviewed studies only reported statistical significance of an overall attention effect collapsed across frequencies. Only a handful of studies have reported statistical significance of individual frequencies (e.g., Chu & D’Zmura, 2019; Steinhauser & Andersen, 2019; Painter et al., 2014; Quigley & Müller, 2014). As such, future work is needed to systematically investigate the effect of frequency choice on feature-based attention effects, particularly for frequencies > 20 Hz.

Task Type and Task Difficulty

Finally, we examined whether the type of task and task difficulty may have influenced our ability to detect an attention effect. In particular, the specific targets that we used may differ slightly from prior work. In our experiment, participants detected a brief period (333 msec) of an, on average, ~75% coherent orientation (the coherent line orientation was a random, unpredictable direction, from 1° to 180°). In this task, participants performed well above chance, but the task was still fairly challenging overall ($d’ = 1.25$). This raises the possibility that, compared with prior SSVEP studies, participants were giving up on some percentage of the trials and that this contributed to the lack of attention effects.

For the reviewed papers in which participants detected a target within the flickering stimulus (“whole-field flicker task” and “hemifield flicker task”), we compiled information about participants’ accuracy, the duration of the target, the type of target, and the percentage of dots/lines that comprised the target (Table S5). We found that our particular task (detect a coherent orientation in the cued color) was slightly different from the other tasks that have been used. Two other prior studies did not use a behavioral task at all: Participants were simply instructed to monitor a particular feature without making any overt response (Zhang et al., 2010; Pei et al., 2002). In three papers, participants attended to a brief (200 msec) luminance decrement in 20% of the attended dots (Adamian et al., 2019; Andersen et al., 2009, 2013). In the remaining papers, participants monitored for a brief coherent motion event (230–500 msec) in 50–85% of the attended dots/lines (Steinhauser & Andersen, 2019; Martinovic & Andersen, 2018; Martinovic et al., 2018; Müller et al., 2006, 2018; Forschack et al., 2017; Quigley & Müller, 2014; Störmer & Alvarez, 2014; Andersen, Müller, & Martinovic, 2012; Andersen & Müller, 2010; Quigley et al., 2010; Andersen et al., 2008).

Although the particulars of the luminance and motion tasks subtly differ from our orientation task, it is not clear why SSVEPs would track attention when the target is a coherent luminance value or motion direction, but not when the target is a coherent orientation. For example, just like in the coherent motion direction tasks used by others,
the angle of the coherent orientation in our task was completely unpredictable. Thus, participants in our task and in other tasks could not form a template of an orientation or motion direction they should attend in advance and instead had to attend to an orthogonal feature dimension such as color. In addition, in both prior tasks and the current task, there were an equal number of coherent events in the cued and uncued color. If participants failed to attend to the cued color and instead responded to any orientation event, their performance in the task would be at chance.

Behavioral performance in the reviewed studies ranged from $d' = 0.8$ to $d' = 3.25$ (Appendix T). In many studies, performance was quite high ($d' > 2$ or accuracy > 90%) relative to performance in our study (Adamian et al., 2019; Steinhauser & Andersen, 2019; Forschack et al., 2017; Quigley & Müller, 2014; Andersen, Müller, & Martinovic, 2012; Andersen et al., 2008, 2009, 2013; Quigley et al., 2010; Müller et al., 2006). However, there were several studies where the authors found SSVEP attention effects despite overall lower behavioral performance values more comparable to our study ($d'$ between 1 and 1.5; Martinovic & Andersen, 2018; Martinovic et al., 2018; Andersen et al., 2015). Sometimes, a more difficult task may actually be associated with increased attention effects: Martinovic and Andersen (2018) observed attention effects that were stronger in the subset of conditions with lower behavioral performance ($d' = .8–1.5$) compared to conditions that were easier ($d' > 2.25$).

**DISCUSSION**

In this preregistered study, we sought to test whether cuing participants to ignore a particular color modulates the time-course of feature-based attention as indexed by SSVEPs. As a baseline point of comparison, we also included a condition in which participants were cued to attend a particular color. This “attend cue” condition was intended as a close replication of much prior work showing that SSVEP amplitudes are modulated by attention (greater amplitude for the attended feature; e.g., Andersen & Müller, 2010; Andersen et al., 2008; Müller et al., 2006). However, we failed to replicate this basic overall attention effect; we found no difference in SSVEP amplitude as a function of attention in either the attend cue or the ignore cue condition. Thus, because we found no overall SSVEP attention effect, we were unable to test our hypotheses about how this attention effect was modulated by being cued to attend versus cued to ignore. Despite the lack of an SSVEP attention effect, positive control analyses indicated that that participants did successfully select the cued target color (i.e., we observed a significantly larger P3 component for target events in the attended color than in the ignored color).

Given our failure to observe an effect of attention on SSVEP amplitude with our task procedures, we performed a focused review of the literature to quantify key methodological aspects of prior studies using SSVEPs to study feature-based attention. Based on this review, we concluded that sample size and trial counts likely did not explain our failure to find an effect; our sample size and trial counts were near the maximum values found in the surveyed literature. Likewise, the range of accuracy values found in the literature suggests that task difficulty does not explain our failure to find an attention effect. However, two key, intentional design differences may have hampered our ability to find an effect: (1) the number of colors in our stimulus set and (2) the frequencies used to generate the SSVEP.

The first key design difference in our study was the number of colors in our stimulus set. We purposefully minimized the influence of intertrial priming on our estimates of feature-based attention (Theeuwes, 2013) by using five unique colors and randomly choosing target and distractor colors on each trial. According to a priming account of feature-based attention, a relatively high proportion of trials where the attended color is repeated back-to-back could inflate or even entirely drive apparent feature-based attention effects. Using five colors somewhat protects against this possibility, because it ensures that the attended color is repeated on 20% of trials, and both the attended/ignored colors are repeated on only 4% of trials. In the literature, we found that most studies had back-to-back color repeats on at least 50% of trials. It is thus plausible that intertrial priming could contribute to observed attention differences in these studies. Contrary to a priming account, however, one study found robust feature-based attention effects using a set of five unique colors (Störmer & Alvarez, 2014), suggesting that participants can use a cue to direct feature-based attention even when the proportion of repeated trials is relatively low. To date, however, no study has directly manipulated the proportion of repeated trials or the number of possible stimulus colors in an SSVEP study. Given emerging evidence that history-driven effects play an important role in shaping both spatial and feature-based attentional selection (Adam & Serences, 2020; Won & Beng, 2020; Failing et al., 2019; Geng et al., 2019; Wang & Theeuwes, 2018a; 2018b; Kadel, Feldmann-Wüstefeld, & Schubö, 2017; Awh, Belopolsky, & Theeuwes, 2012), we think that future work is needed to directly investigate whether and to what degree SSVEP estimates of feature-based attention are modulated by intertrial priming.

The second key design difference in our study was the chosen set of frequencies. To ensure adequate temporal resolution to characterize time-course effects, we chose to use slightly higher frequencies (24 and 30 Hz). We believed these values would be reasonable, because an initial study of the time-course of spatial attention used SSVEP frequencies in a similar range (20 and 28 Hz; Müller, Teder-Sälejärvi, et al., 1998). In addition, frequencies in the beta band (~15–30 Hz) have commonly been used in other SSVEP studies of spatial attention (Won, Hwang, Dähne, Müller, & Lee, 2016; García et al., 2013; Kashiwase, Matsumiya, Kuriki, & Shiioiri, 2012; Toffanin, de Jong, Johnson, & Martens, 2009; Müller & Hillyard, 2000; Müller, Ficton, et al., 1998), and SSVEPs are
overall robust using a wide array of frequencies (at least 1–50 Hz; Zhu, Bieger, Garcia Molina, & Aarts, 2010; Herrmann, 2001). However, some spatial attention studies have found no attentional modulation of SSVEPs in the beta band (Antonov, Chakravarthi, & Andersen, 2020; Gulbinaite, Roozendaal, & VanRullen, 2019), or have found effects only for the second harmonic of beta band frequencies (Vissers et al., 2017; Garcia et al., 2013; Kim et al., 2007). Furthermore, the SSVEP amplitude, estimated spatial extent of the SSVEP signal, and the size of spatial attention effects vary with frequency (Gulbinaite et al., 2019; Ding et al., 2006; Herrmann, 2001). Given differences in the cortical processing of locations and features (Cohen & Maunsell, 2011; Kastner & Ungerleider, 2000; Owen, Milner, Petrides, & Evans, 1996; Haxby et al., 1994; Mishkin & Ungerleider, 1982) and differences in SSVEP spatial extent and strength with frequency (Gulbinaite et al., 2019; Lithari, Sánchez-García, Ruhnau, & Weisz, 2016; Ding et al., 2006), it is plausible that feature-based attention can only be tracked with a limited range of frequencies (e.g., frequencies near the alpha band). Future work will be needed to systematically investigate the effect of SSVEP frequency on feature-based attention.

It is perhaps puzzling that frequencies above 20 Hz have been commonly used in the spatial attention literature but have not been used in the feature-based attention literature. The truncation of the frequency distribution in the reviewed literature could be a piece of the “file drawer” in action. It is possible that other researchers likewise discovered that they were unable to track feature-based attention using certain frequencies, but that these null results were never published because of journals’ and authors’ biases toward publishing positive results (Franco, Malhotra, & Simonovits, 2014; Ferguson & Heene, 2012; Dwan et al., 2008; Cooper, DeNeve, & Charlton, 1997; Dickersin, Min, & Meinert, 1992; Dickersin, 1990; Rosenthal, 1979) and biases against publishing negative results (i.e., “censoring of null results”; Guan & Vandekerckhove, 2016; Sterling, Rosenbaum, & Weinkam, 1995; Sterling, 1959). Thus, our results highlight the practical and theoretical importance of regularly publishing null results. On the practical side, if prior null results had been published, we may have better known which frequencies to use or avoid, and we would have been able to test our key hypotheses. On the theoretical side, our results highlight how seemingly unimportant null results can have implications for theory when viewed in the context of the broader literature. For example, if certain frequencies track spatial but not feature-based attention, this may inform our understanding of the brain networks and cognitive processes differentially modulated by flicker frequency (Ding et al., 2006; Srinivasan et al., 2006).

In short, we found no evidence that SSVEPs track the deployment of feature-based attention with our procedures, and future methodological work is needed to determine constraints on generalizability of the SSVEP method for tracking feature-based attention. We performed a focused review of prior studies using SSVEPs to study feature-based attention, and from this review, we identified two key factors (frequencies used; likelihood of intertrial feature priming) that should be systematically investigated in future work.

Appendix A. Example frames during the stimulus presentation. Eight example frames (1–8) from the stimulus presentation period illustrate how the flicker was achieved (refresh rate was 120 Hz, so each frame was ~8.33 msec). In this example, the attended color is yellow, and the attended frequency is 24 Hz (three frames on, two frames off). Blue is the unattended color (30 Hz; two frames on, two frames off). The white dot in the upper left-hand corner was used to record the attended frequency flicker using a photodiode (this corner of the screen was covered with thick, opaque black electrical tape so that it was not visible to the participants.)
Appendix B. Accuracy for target-present trials as a function of the time between cue onset and the target onset. For short cue-target intervals (≤ 275 msec), participants were more accurate for attend cues than ignore cues. This pattern suggests that participants were more quickly able to utilize the attend cue than the ignore cue. Shaded error bars indicate ± 1 SEM. Small gray dots indicate p < .05 (uncorrected), and large dots indicate p < .001 (uncorrected).

Appendix C. Power and SNR for each frequency. (A) Power for each frequency using the Gaussian wavelet filter analysis. (B) SNR for each frequency, calculated as the power at the frequency (e.g., 24 Hz) divided by the power at the average of the two neighboring 1-Hz frequencies on either side (e.g., average of 22, 23, 25, and 26 Hz). The theoretical chance level for SNR is 1 (dotted line), but because SNR is calculated with neighboring frequencies, frequencies that are adjacent to a significant “peak” may have values below 1. (C) Cohen’s d for the comparison between SNR at each of the two target SSVEP frequencies (24 Hz, 30 Hz) relative to other baselined frequencies (3–33 Hz excluding frequencies within ± 2 Hz of the target SSVEP frequencies).

Appendix D. Time-course of SNR for each frequency. The stimulus began flickering at −1333 msec, and the cue indicating which color to attend appeared at 0 msec. Red lines show when 24 Hz was the attended frequency; blue lines show when 30 Hz was the attended frequency. Solid lines show data from the “attend cue” condition; dotted lines show the “ignore cue” condition.
Appendix E. Frequency spectra separately for each target/distractor presence condition. Trials were counterbalanced to have a 50% chance of having a target event (T1) and to have 50% chance of including a distractor event (D1). Thus, 25% of trials had neither a target nor distractor (T0D0), 25% of trials had a target only (T1D0), 25% of trials had a distractor only (T0D1), and 25% of trials had both a target and a distractor (T1D1). Frequency spectra for each subcondition are shown (rows: attend cue or ignore cue; columns: each combination of target and distractor present/absent).

Appendix F. SNR values separately for each target/distractor presence condition. Trials were counterbalanced to have a 50% chance of having a target event (T1) and to have 50% chance of including a distractor event (D1). Thus, 25% of trials had neither a target nor distractor (T0D0), 25% of trials had a target only (T1D0), 25% of trials had a distractor only (T0D1), and 25% of trials had both a target and a distractor (T1D1). Frequency spectra for each subcondition are shown (rows: attend cue or ignore cue; columns: each combination of target and distractor present/absent). The bottom row of asterisks shows post hoc, uncorrected significance for overall SSVEP signal compared to a null value of 1. The SSVEP signal was overall highly significant (***, p < .001). The top row of asterisks shows post hoc, uncorrected significance for the comparison between the two adjacent bars (ns, p > .10, ~p < .10, *p < .05). Note, no conditions showed an attention effect (attended frequency > ignored frequency); the only significant, uncorrected post hoc comparison was in the wrong direction (ignored > attended).
Appendix G. Power by frequency separately for each color distance condition. Target and distractor colors were randomly assigned on each trial from a pool of five possible colors. Thus, the target and distractor colors could be either 72° (Color 1) or 144° (Color 2) apart on a color wheel. We found no evidence of an attention effect in either color distance condition.

Appendix H. An additional analysis variant for the main SNR measure: skipping the first bin for computing SNR. Rather than using the preregistered frequencies of ±1 and ±2 Hz for computing SNR, we instead skipped the first 1-Hz bin. Because ±1 Hz had greater than baseline power, we may have attenuated our ability to observe SSVEP-related differences by including this bin in our SNR subtraction. For this analysis variant, we instead calculated SNR as the peak frequency minus the average of all frequencies ±2 and ±3 Hz from the peak (e.g., to compute SNR for 24 Hz, we subtracted the mean power at 21, 22, 26, and 27 Hz). Although overall SNR was much higher across all conditions using this metric, the pattern across experimental conditions was unchanged (i.e., we found no significant attention effects).
Appendix J. Violin plot of the second harmonic frequencies 48 and 60 Hz from the FFT analysis. (Left) Violin plot of SNR for the second harmonic frequencies in the “attend cue” condition; SNR for both harmonics was greater than 1, but there were no attention effects. (B) Violin plot of SNR for the second harmonic frequencies in the “ignore cue” condition; SNR for both harmonics was greater than 1, but there were no attention effects.
Appendix K. RESS analysis likewise shows null attention effects. After code associated with [1], we performed RESS on our data to ensure that our a priori choice of electrodes did not impede our ability to find an attention effect. We decided to stick very closely to the default settings for RESS code developed by others to take some “researcher degrees of freedom” out of the equation. We obtained a highly consistent pattern of results despite using a data-driven, single-trial approach that differs substantially from our preregistered trial-averaged approach. We also note that the SNR values from the RESS approach are lower than the trial-averaged FFT we present in the main analysis, but that RESS does still provide an SNR advantage when compared to a single-trial FFT approach, as in [1]. We first calculated the spatial filters using data from all trials and the full trial length (−1000 to 2000 msec). We then applied the spatial filters to calculate SNR for each condition of interest (e.g., “Attend 24 Hz, Attend Cue Condition,” 24-Hz RESS time series; 500–2000 msec). For the analysis, we used a frequency resolution of 0.5 Hz, an FWHM of 0.5 Hz for the center frequency, an FWHM of 1 Hz for the neighboring baseline frequencies ± 2 Hz from the peak frequency. SNR was calculated as the ratio between each frequency of interest and the frequencies ± 2 Hz away. (A) Normalized SNR by frequency and topography of the RESS time series optimized for 24 Hz (red) and 30 Hz (blue), collapsed across all conditions. (B) SSVEP response (computed as normalized SNR) for the 24-Hz optimized RESS time series in the attend cue condition and ignore cue condition. (C) SSVEP response (computed as normalized SNR) for the 30-Hz optimized RESS time series in the attend cue condition and ignore cue condition. We again found no significant effects of attention for either SSVEP frequency.
Appendix L. Violin plots of values obtained from the RESS analysis. We found no effect of attention on RESS values in either the attend cue condition (left panel) or the ignore cue condition (right panel).

Appendix M. Violin plots of SNR values for each frequency, calculated from an FFT analysis on accurate trials only. Performing an FFT analysis on accurate trials only likewise yields null attention effects both in the attend cue condition (left panel) and the ignore cue condition (right panel).
Appendix N. Results of the PLI analysis. We performed an FFT on single trials rather than on condition-averaged waveforms (time window: 333–2000 msec), and we extracted single-trial phase values (\textit{angle.m}). We calculated a PLI by computing mean-resultant vector length on histograms of single-trial phase values (separate histograms for each condition, electrode, and frequency). Mean-resultant vector length ranges from 0 (fully random values) to 1 (perfectly identical values), for reference, see: Zar (2007). (A) PLI as indexed by mean-resultant vector length, averaged across electrodes O1, O2, and Oz. Replicating prior work, we found robust PLI values at the two SSVEP frequencies (24 and 30 Hz). (B) However, we found no evidence that PLI values were modulated by attention in the expected direction.

Appendix O. P3 component at electrodes Pz and POz, split by whether or not a response was made. (A) No response made, “attend cue” condition. (B) No response made, “ignore cue” condition. (C) Response made, “attend cue” condition. (D) Response made, “ignore cue” condition. Shaded error bars represent \textit{SEM}.

</tbody>
</table>

To test if the difficulty of our task may have contributed to our null results, we examined behavior from studies in which participants monitored for a target in the flickering stimulus (i.e., whole-field and hemifield flicker tasks). We also noted the type of target and how long it was on the screen.

^a Values were not listed in the text, so some values were approximated based on the figures (e.g., hit rates or $d'$ depicted in a bar graph).

^b Analyzed harmonics (2F, 4F) but not the fundamental frequency. 2F, but not 4F, had a significant attention effect.

^c Attention modulation scores were only compared across conditions, not to baseline; they were presumably significant overall, but this was not formally tested.
Diversity in Citation Practices

A retrospective analysis of the citations in every article published in this journal from 2010 to 2020 has revealed a persistent pattern of gender imbalance: Although the proportions of authorship teams (categorized by estimated gender identification of first author/last author) publishing in the Journal of Cognitive Neuroscience (JoCN) during this period were M(an)/M = 0.408, W(oman)/M = 0.335, M/W = 0.108, and W/W = 0.076 (Fulvio et al., JoCN, 33:1, pp. 5–7). Consequently, JoCN encourages all authors to consider gender balance explicitly when selecting which articles to cite and gives them the opportunity to report their article’s gender citation balance.

Note

1. As we did not preregister Bayesian analysis choices (choices about priors, etc.), we did not calculate a Bayes factor for this preregistered analysis. However, the post hoc power analysis gives a sense of the degree to which this is a null effect.
